out, if we were carrying a heavy suitcase in a changing gravitational field, we could observe the changes of the Gao of the metric tensor.

I conclude that our drawing of the observational-theoretical line at any given point is an accident and a function of our physiological make-up, our current state of knowledge, and the instruments we happen to have available and, therefore, that it has no ontological significance whatever.

NOTES

3. I have borrowed the hammer analogy from E. Nagel, "Science and [Feigl's] Semantic Realism," Philosophy of Science, XVII (1950), 174–81. I have been influenced by it but it should be pointed out that Professor Nagel makes it clear that he does not necessarily subscribe to the view which he is explaining.

5. I am not attributing to Professor Bermann the absurd views suggested by these questions. He seems to take a sense-datum language as his observation language (the base of what he called "the empirical hierarchy"), and, in some ways, such a position is more difficult to refute than the one which purports to take an "observable-physical-object" view. However, I believe that destroying the straw men with which I am now dealing amounts to desirable preliminary work.

6. For arguments that it is possible to alter a theory without altering the meaning of its terms, see my "Meaning Postulates in Scientific Theory," in Current Issues in the Philosophy of Science, eds. Feigl and Maxwell.

7. The reader is no doubt familiar with the abundant literature concerned with this issue. See, for example, Sellars's "Empiricism and the Philosophy of Mind," which also contains references to other pertinent work.

8. We may say "noninferentially" decide, provided this is interpreted liberally enough to avoid starting the entire controversy about observability all over again.

9. Cf. Sellars, "Empiricism and the Philosophy of Mind." As Professor Sellars points out, this is the crux of the "other-minds" problem. Sensations are epistemic states (relative to an intersubjective observational language, I would add) are theoretical entities (and they "really exist") and not merely actual and/or possible behavior. Surely it is the unwillingness to countenance theoretical entities—the hope that every sentence is translatable not only into some observation language but the physical-language—which is responsible for the "logical behaviorism" of the neo-Wittgensteins.

A couple of years ago I was discussing scientific realism with Dr. Jal Parakh, a biologist from Western Washington University. We had talked about many of the things that philosophers find important. He diffidently added that, from his point of view, a main reason for believing in the existence of entities postulated by theory is that we have evolved better and better ways of actually seeing them. I began to protest against this naive instinct that bypasses the philosophical issues, but I had to stop. Isn't what he says right?

Last fall, during a lecture in Stanford University's "Microscopy for Biologists" course, the professor, Dr. Paul Green, casually remarked that "X-ray diffraction microscopy is now the main interface between atomic structure and the human mind." Dr. Green is a nuts and bolts man, not given to philosophizing. Philosophers of science who discuss realism and anti-realism must needs know a little about the instruments that inspire such eloquence. What follows is a first start, which limits itself to biology and which hardly gets beyond the light microscope. Even then it is a marvel of marvels which, I suspect, not many philosophers well understand. Microscopes do not work in the way that most uninitiated people suppose. But why, it may be asked, should a philosopher care how they work? Because a correct understanding is necessary to elucidate problems of scientific realism as well as answering the question posed by my title.

Our philosophical literature is full of intricate accounts of causal theories of perception, yet they have curiously little to do with real life. We have fantastical descriptions of aberrant causal chains which, Gettier-style, call in question this or that conceptual analysis. But the modern microscope has far more amazing tricks than the most imaginative of armchair students of perception. What we require in philosophy is better awareness of the truths that are stranger than fictions. We ought to have some understanding of those astounding physical systems "by whose augmenting power we now see more/than all the world has ever done before."

THE GREAT CHAIN OF BEING

Philosophers have written dramatically about telescopes. Galileo himself invited philosophizing when he claimed to see the moons of Jupiter, assuming that the laws of motion in the celestial sphere are the same as those on earth. Paul Feyerabend has used that very case to urge that great science proceeds as much by propaganda as by reason: Galileo was a con man, not an experimental reasoner. Pierre Duhem used the telescope to present his famous thesis that no theory need ever be rejected, for phenomena that don't fit can always be accommodated by changing auxiliary hypotheses (if the stars aren't where theory predicts, blame the telescope, not the heavens). By comparison the microscope has played a humble role, seldom used to generate philosophical para-
PHILOSOPHERS OF THE MICROSCOPE

Every twenty years or so a philosopher has said something about microscopes. As the spirit of logical positivism came to America, one could read Gustav Bergman telling us that as he used philosophical terminology, microscopic objects are not physical things in the usual sense. They are, by courtesy of language and pictorial imagination. ... When I look through a microscope, I see it as a patch of color which creeps through the field like a shadow over a wall. 

I think that means that we do not see, in any ordinary sense of the word, with a microscope.

DON'T just PEER: INTERFERE

Philosophers tend to look on microscopes as black boxes with a light source at one end and a hole to peer through at the other. There are, as Grover Maxwell puts it, low power and high power microscopes, more and more the same kind of thing. That's not right, nor are they experiments for looking through. In fact a philosopher will certainly not see through a microscope until he has learned to use several of them. Asked to draw what he sees he may, like James Thurber, draw his own reflected eyeball, or, like Gustav Bergman, see only "a patch of color which creeps through the field like a shadow over a wall." He will certainly not be able to tell how far a dust particle or a salivary gland until he has started to dissect a fruit fly under a microscope of modest magnification.

That is the first lesson: you learn to see through a microscope by doing, not just by looking. There is a parallel to Berkeley's New Theory of Vision, according to which we have three-dimensional vision only after learning what it is to move around in the world and inanimate objects are correlated with our allegedly two dimensional retinal image, and this learned cueing produces three-dimensional perception. Likewise, learning to use a microscope may not be just passive looking.

The conviction that a particular part of a cell is there as imaged is, says the least, reinforced when, using straightforward physical means, you microinject a fluid into that part of the cell. We see the tiny glass needle—a tool that we have ourselves hand crafted under the microscope—jerk through the cell wall. We see the lipid oozing out of the end of the needle as we gently turn the micrometer screw on a large, thoroughly macroscopic, plunger. Blast! Inept as I am, I have just burst the cell wall, and must try again on another specimen. John
Dewey's jeers at the "spector theory of knowledge" are equally germane for the spectator theory of microscopy.

This is not to say that practical microscopists are free from philosophical perplexity. I quote from the most thorough of available textbooks intended for biologists:

[B] The microscopist can observe a familiar object in a low power microscope and see a shadow which is "the same as" the object. Increase of magnification may reveal details in the object which are invisible to the naked eye; it is natural to assume that they also, are "the same as" the object. (At this stage it is necessary to establish that detail is not a consequence of damage to the specimen during preparation for microscopy.) But what is actually implied by the statement that "the image is the same as the object?"

The use of the word "image" is a purely optical effect. The "sameness" of object and image in fact implies that the physical interactions with the light beam that render the object visible to the eye (or would render it visible, if large enough) are identical with those that lead to formation of an image in the microscope.

Suppose however, that the radiation used to form the image is a beam of ultraviolet light, x-rays, or electrons, or that the microscope employs some device which converts differences in phase into changes in intensity. The image then cannot possibly be "the same" as the object, even in the limited sense just defined! The eye is unable to perceive ultraviolet, x-ray, or electron images, so to detect shifts of phase between light beams...

This line of thinking reveals that the image must be a map of interactions between the specimen and the imaging radiation.

The author goes on to say that all of the methods she has mentioned, and more, "can produce 'true' images which are, in some sense, "same." She also remarks that in a technique like the radioautograph, "one obtains an 'image' of the specimen. obtained exclusively from the point of view of the location of radioactive atoms. This type of 'image' is so specialized as to be, generally, uninterpretable without the aid of an additional image, the photomicrograph, upon which it is superseded."

This microscopist is happy to say that we see through a microscope only when the physical interactions of specimen and light beam are "identical" for image formation in the microscope and in the eye. Contrast my professional training [A] from that of the same kind of thing. I would like to correct that idea.

Leeuwenhoek, hardly the first microscopist, was a technician of genius. His scopes had flaws, but he made a lens for each specimen to be examined. The object was mounted upon a pin at just the right distance. We don't quite know how he made such marvelously accurate drawings of his specimens. The most representative collection of his lenses-plus-specimen was given to the Royal Society in London, which lost the entire set after a century or so in what are politely referred to as suspicious circumstances. Entering by that time the conflation results from geometrical optics, in which one diagrams the system with a specimen in focus and an "image" in the other focal plane, where the "image" indicates what you will see if you reverse the light rays. The clue for his specimens had lost its strength, and the objects had begun to fall off their pins. Almost certainly Leeuwenhoek got his marvelous results thanks to a secret of illumination rather than to lens manufacture, and he seems never to have taught the public his technique. Perhaps Leeuwenhoek invented dark field illumination, rather than the microscope. That guess should serve as the first of a long series of possible reminders that many of the chief advances in microscopy have had nothing to do with optics. We have needed microscopes to slice specimens, perceive with the eye or with a pure light sources, and, at more modest levels, the screw micrometer for adjusting focus, fixatives and centrifuges.

Although the first microscopes did create a life; they were only showing worlds within worlds, it is important to note that after Hooke's compound microscope, the technology did not markedly improve. Nor did much new knowledge follow after the excitement of the initial observations. The microscope became a toy for English ladies and gentlemen. The toy would consist of a microscope and a box of mounted specimen slides. Note that a box of mounted slides might well cost more than the purchase of the microscope itself. You did not just put a drop of pond water on a slip of glass and look at it. All but the most expert would require a ready mounted slide to see anything. Indeed considering the optical aberrations it is amazing that anyone ever did see anything through a compound microscope, although in fact, as always in experimental science, a really skillful technician can do wonders with awful equipment.

These are about eight chief aberrations in back and back light microscopes, two important ones are spherical and chromatic. The former is the result of the fact that you polish a lens by random rubbing. That, as can be proven, gives you a spherical surface. A light ray travelling at a small angle to the axis will not focus at the same point as a ray closer to the axis. For angles i for which sin i differs at all from we get no common focus if the light rays. We have men can be seen only as a smear through the microscope. This was well understood by Huygens, who also knew how to correct it in principle, but practical combinations of achromatic and achromatic microscopes were a long time in the making.

Chromatic aberrations are caused by differences in wavelengths of light of different colors. Light emanating from the same point on the specimen will come to focus at different points. A sharp red image is superimposed on a blue smear. A high powered optical device like a microscope, and anyone interested in finding a microscope about the house for entertainments, it is no wonder that serious science had nothing to do with the instrument. We often regard Bichat as the founder of histology, the study of living tissues. In 1800 he would not allow a microscope in his lab.

When people observe in conditions of obscurity each sees in his own way and according as he is affected. It is, therefore, observation of the vital properties that must guide us rather than the blurred images provided by the best of microscopes.

No one tried very hard to make achromatic microscopes, because Newton
had written that they are physically impossible. They were made possible by the advent of flint glass, with refractive indices different from that of ordinary glass. A doublet of lenses of different refractive indices is used to cancel out the aberration perfectly for a given pair of red and blue wavelengths, and although the solution is imperfect over the whole spectrum, it is pretty negligible and can be improved by a triplet of lenses. The first person to get the right ideas was so secretive that he sent the specifications for the lenses of different kinds of glass to two different contractors. They both subcontracted with the same artist, who then formed a shrewd guess that the lenses were for the same device. In due course, in 1758, the idea was pirated. A court case for the patent rights was decided in favor of John Dolland. The High Court Judge ruled:

It was not the person who locked the invention in his storehouse that ought to profit by a patent for such an invention, but he who brought it forth for the benefit of the public.  

The public did not benefit all that much. Even up in to the 1860s there were serious debates as to whether globules seen through a microscope were artefacts of the instrument or genuine elements of living material. (They were artefacts.) Microscopes did get better and microscopy improved at a rather greater rate. If we draw a graph of development we get a first high around 1660, then a slowly ascending plateau until a great leap around 1870, the next great period, which is still going on about 1945. An historian has plotted this graph with great precision, using as a scale the limits of resolution of surviving instruments of different epochs. Making a subjective assessment of great applications of the microscope, we would draw a similar graph, except that the 1870/1660 contrast would be greater. Few truly memorable facts were found out with a microscope until after 1860. The surge of new microscopy is partly due to Abbe, but the most immediate cause of advance was the availability of aniline dyes for staining. Living matter is mostly transparent. The new aniline dyes made it possible for us to see microbes and much else.

ABBE AND DIFFRACTION

How do we "normally" see? Mostly we see reflected light. But if we are using a magnifying glass to look at a specimen illuminated from behind, then it is transmission, or absorption, that we are "seeing." So we have the following idea: To see something through a light microscope is to see patches of dark and light corresponding to the proportions of light transmitted or absorbed. We call this action of the light rays. I think that even Huygens knew there is something wrong with this conception, but not until 1873 could one read in print how a microscope works.

Ernst Abbe was the happiest example of a rags-to-riches story. Son of a spinning-mill workman, he yet learned mathematics and was sponsored through the Gymnasium. He became a lecturer in mathematics, physics, and astronomy. His optical work led him to associate. He was taken on by the small firm of Carl Zeiss in Jena, and when Zeiss died he became an owner; he retired to Jena of philanthropy. Innumerable mathematical and practical innovations by Abbe turned Carl Zeiss into the greatest of optical firms. Here I consider only one.

Abbe was interested in resolution. Magnification is worthless if it "magnifies" two distinct dots into one big blur. One needs to resolve the dots into two distinct images. G. B. Airy, the English Astronomer Royal, had seen the point already when considering the properties of a telescope needed to distinguish twin stars. It is a matter of diffraction. The most familiar example of diffraction is the fact that shadows of objects with sharp boundaries are fuzzy. This is a consequence of the wave character of light. When light travels between two narrow slits, some of the beam may go straight through, but some of it will bend off at an angle to the main beam, and some more will bend off at a larger angle: these are the first-order, second-order, and higher-order beams.

Abbe took as his problem how to resolve (i.e., visibly distinguish) parallel lines on a diatom. These lines are very close together and of almost uniform separation and width. He was soon able to take advantage of even more regular artificial diffraction gratings. His analysis is an interesting example of the way in which pure science is applied when it works out the theory for the case of looking at a diffraction grating, and inferred that this represents the infinite complexity of the physics of seeing a heterogeneous object with a microscope.

We see changes in the way the light is diffracted, but most of it is diffracted rather than transmitted. It is emitted from the grating at the angle of first, second, or third order diffractions, where the angles of the diffracted rays are in multiples of the angle of the distances between the lines on the grating. Abbe realized that in order to see the slits on the grating, one must pick up not only the transmitted light, but also at least the first order diffracted ray. What he did, in fact, is best represented as a Fourier synthesis of the transmitted and the diffracted rays. Thus according to Abbe the image of the object is produced by the interference of the light waves emitted by the object, the principal image, and the secondary images of the light source which are the result of diffraction.

Practical applications abound. Evidently you could use the diffracted rays by having a wider aperture for the objective lens, but then you obtain vastly more spherical aberration as well. Instead you can change the medium between the specimen and the lens. With something denser than air, as in the oil immersion microscope, you capture more of the diffracted rays within a given aperture and so increase the resolution of the microscope.

When Abbe-Zeiss microscopes were good, the theory was resisted for a number of years, particularly in England and America, who had enjoyed a century of dominating the market. Even by 1910 the very best English microscopes, built on purely empirical experience, were not as good as Abbe's, and the Zeiss model could resolve as well or better than the Zeiss equipment. The expensive craftsmen with trial-and-error skills were doomed. It was not, however, only commercial or national rivalry which made some people resist to believe Abbe. In an American textbook of 1916 I find it stated that an alternative (and more "common sense") theory of "ordinary" vision is now once again in the ascendant and will soon supplant Abbe's. Then I rose partly from surprise at what Abbe asserted, with the apparent consequence that, as quotation [A] has it, "there is and can be no comparison between microscopic and macroscopic vision."

If you hold (as my more modern quotation [B] still seems to hold), that what we see is essentially a matter of a certain sort of physical process, then perhaps nothing else must be more in the domain of optical illusion or at best of mapping. On that account the systems of Leeuwenhoek and of Hooke do allow you to see. After all, Abbe even the conventional light microscope is essentially a Fourier synthesizer of first or even second order diffractions. Hence you must modify your notion of seeing or hold that you never see through a serious microscope. I do not reach a conclusion on this question, we had best examine some more recent instruments.

A PLETHORA OF SCOPES

We move on to alter World War II. Most of the ideas had been around during the interwar years, but did not get beyond prototypes until later. One invention was a good deal older, but it was not properly exploited for a while.

The first practical problem for the cell biologist is that the animal cell does not show up under an ordinary light micro-
The differential interference-contrast technique is distinguished by the following characteristics. Both clearly visible outlines (edges) within the object and continuous structures (striae) are imaged in their true profile.

So says a Carl Zeiss sales catalogue to hand. What makes the enthusiastic sales person suppose that the images produced by these several optical systems are "true"? Of course, the images are "true" only when one has learned to put aside distortions. There are many grounds for the conviction that a perceived bit of structure is real or true. One of the most natural is the most important. I shall illustrate it with my own first experiment. Low-powered electron microscopy reveals small dots in red blood cells. These are called dense bodies: that means simply that they are electron-dense and show up on a transmission electron microscope without any preparation or staining whatsoever. On the basis of the movements and densities of these bodies in various stages of cell development or disease, it is guessed that they may have an important part to play in blood biology. On the other hand they may simply be artefacts of the electron microscope. One test is obvious: can one see these selfsame bodies using a different physical technique? In this case the problem is fairly readily solved. The low resolution electron microscope is about the same power as a high resolution light microscope. The dense bodies do not show up on this technique, but are revealed by fluorescent staining and subsequent observation by the fluorescent microscope.

The difference between fluorescence microscopy and light microscopy is perhaps easier to understand. The light source is simply split by a half-silvered mirror, and half the light goes through the specimen while half is kept as an unaffected reference wave to be recombined for the output image. Changes in optical path due to different refractive indices within the specimen thus produce interference effects with the reference beam.

The interference microscope is attended by illusory images but is particularly valuable because it provides a quantitative determination of refractive indices within the specimen. Naturally once we have such devices in hand, endless variations may be constructed, such as polarization interference microscopes, multiple beam interference phase modulation, and so forth.

When we stick to light there is lots to do. Ultraviolet microscopy doubles resolving power, although its chief interest lies in noting the specific ultraviolet absorption and diffraction. We could use any property of light that interacts with a specimen in order to study the structure of the specimen. Indeed we could use any property of any kind of wave at all.

Even when we stick to light there is lots to do. Ultraviolet microscopy doubles resolving power, although its chief interest lies in noting the specific ultraviolet absorption and diffraction. We could use any property of light that interacts with a specimen in order to study the structure of the specimen. Indeed we could use any property of any kind of wave at all.
COINCIDENCE AND EXPLANATION

Arguments from coincidence have been put to more general use in discussions of scientific realism. In particular J. J. C. Smart notes that good theories are used to explain diverse phenomena. It would, he says, be a cosmic coincidence if the theory were false and yet correctly predicted all the phenomena:

One would have to suppose that there were unnumerable lucky accidents about the behavior mentioned in the theoretical vocabulary, so that they behaved miraculously as if they were brought about by the non-existent things ostensibly talked about in the theoretical vocabulary.\(^\text{15}\)

Van Fraassen challenges this and related arguments for realism that deploy what Gilbert Harman calls “inference to the best explanation,” or what Hans Reichenbach and Wesley Salmon call the “common cause” argument. So it may seem as if my talk of coincidence puts me in the midst of an ongoing feud. Not so! My argument is much more localized, and commits me to none of the positions of Smart or Salmon.

First of all, we are not concerned with an observational and theoretical vocabulary. There may well be no theoretical vocabulary for the things seen under the microscope—“dense body” means nothing else than something dense, i.e., that shows up under the microscope, and is distinguished from the body of which it is a part. There are no such standard techniques as the electron microscope or fluorescent staining, and it is no “explanation” of this to say that some definite kind of thing (whose nature is as yet unknown) is responsible for the persistent arrangement of dots. Thirdly we have no theory which predicts some wide range of phenomena. The fourth and perhaps most important difference is this: we

are concerned to distinguish artefacts from real objects. In the metaphysical disputes about realism, the contrast is between “real” although “unobservable” entities and “not a real entity, but rather a tool of thought.” With the microscope we know there are dots on the micrograph. The question is, are they artefacts of the physical system or are they structure in the specimen itself? My argument from coincidence says simply that it would be a preposterous coincidence if two totally different kinds of physical systems were to produce exactly the same arrangements of dots on micrographs.

THE ARGUMENT OF THE GRID

I now venture a philosopher’s aside on the topic of scientific realism. Van Fraassen says we can see through a telescope because although we need the telescope to see the moons of Jupiter when we are positioned on earth, we could go out there and look at the moons with the naked eye. Perhaps that fantasy is close to fulfillment, but it is still science fiction. The microscope avoids fantasy. Instead of flying to Jupiter he shrinks the visible world. Consider the grid that we used for re-identifying dense bodies. The tiny grid is made of metal; then it is barely visible to the naked eye. They are made by drawing a very large grid with pen and ink. Letters are neatly inscribed by a draftsman at the corner of each square on the grid. Then the grid is made photographically. Using what are now standard techniques, metal is deposited on the resulting micrograph. Grids are sold in packets, or rather tubes, of 100, 250, and 1,000. The procedures for making such grids are entirely well understood, and as reliable as any other high-quality mass production system.

In short, rather than dispourng ourselves to Jupiter in an imaginary space ship, we are routinely shrinking down to the grid. Then we look at the tiny disc through almost any kind of microscope and see exactly the same shapes and letters as were drawn in the large by the first draftsman. It is impossible seriously to entertain the thought that the minute disc, which I am holding by a pair of tweezers, does not in fact have the structure of a label or an artefact of the specimen itself.

It was once not only possible but perfectly sensible to ban the microscope from the histology lab on the plain grounds that it chiefly revealed artefacts of the optical system rather than the structure of fibers. That is no longer the case. It is always possible in innovative microscopy to become convinced that what you are seeing is really in the specimen rather than an artefact of the preparation of the optics. But by 1981, as opposed to 1800, we have a vast arsenal of ways of gaining such conviction. I emphasize only the “visual” side. Even there I am simplistic. I say that if you can see the same functional features of structure using different non-grid systems, you have excellent reason for saying, “that’s real” rather than, “that’s an artefact.” It is not the case, however, that on the black patches of the cell membrane or the green patches on the tarmac road are seen, on a hot day, from a number of different perspectives, but always in the same location, one concludes that one is seeing puddles rather than the familiar illusion. One may still be wrong. One is wrong, from time to time, in microscopy, too. Indeed the sheer similarity of the kinds of mistakes made in macroscopic and microscopic perception may increase the possibility that one sees through a microscope.

I must repeat that just as in large scale vision, the actual “images” or micrographs are only one small part of the confidence in reality. In a recent article, a molecular biologist G. S. Stent recalled that in the late forties or early fifties Life magazine had a full color cover of an electron micrograph, labelled, excitedly, “the first photograph of the gene.”\(^\text{16}\) Given the theory, or lack of theory, of the gene at that time, said Stent, the title did not make any sense. Only a greater understanding of what a gene is can bring the conviction that it shows what the actual micrographs show. We become convinced of the reality of bands and interbands on chromosomes
not just because we see them, but because we formulate conceptions of what they do, what they are for. But in this respect, too, microscopic and macroscopic visions are not different. In the Congo we won't see much if the bizarre new environment until he starts to get some idea what is in the jungle.

Thus I do not advance the argument from coincidence as the sole basis of our conviction that we see true through the microscope. It is one element, a compelling visual element, that combines with more intellectual modes of understanding, and with other kinds of experimental work. Biological microscopy without practical biochemistry is as blind as Kant's intuitions in the absence of concepts.

THE ACOUSTIC MICROSCOPE

I here avoid the electron microscope. There is no more "the" electron microscope than there is a "the" light microscope: all sorts of different properties of electron beams are used. A simple but comprehensive explanation requires another essay. In case, however, we have in mind too slender a diet of examples based upon the properties of visible light, let us briefly consider the most disparate kind of radiation imaginable: sound.13

Radar is used for aerial warfare, and sonar, invented for war at sea, remind us that longitudinal and transverse wave fronts can be put to the same kinds of purpose. Ultrasound is "sound" of very high frequency. Ultrasound examination of the fetus in utero has recently won well deserved publicity. Over forty years ago Soviet scientists suggested a microscope using sound of frequency 1000 times greater than audible noise. Technology has only recently caught up to this idea. Useful prototypes are just now in operation.

The acoustic part of the microscope is relatively simple. Electric signals are converted into sound signals and then, after interaction with the specimen, are reconverted into electricity. The subtlety of present instruments lies in the electronics rather than the acoustics. The acoustic microscope is a scanning device. It produces its images by converting the signals into a spatial display on a television screen, a micrograph, or, when studying a large number of cells, a videotape.

As always a new kind of scope is interesting because of the strange aspects of a phenomenon that it may reveal. Changes in refractive index are vastly greater for sound than for light. Moreover sound is transmitted through objects that are completely opaque. Thus one of the first applications of the acoustic microscope is in metallurgy, and also in detecting defects in silicon chips. For the biologist, the prospects are also striking. The acoustic microscope is sensitive to density, viscosity, and flexibility of living matter. Moreover the very short bursts of sound used by the scanner do not immediately damage the cell. Hence one may study the life of a cell in a quite literal way: one will be able to observe changes in viscosity and flexibility as the cell goes about its business.

The rapid development of acoustic microscopy leaves us uncertain where it will lead. A couple of years ago the research reports carefully denied any competition with electron microscopies; they were glad to give resolution at about the level of light scopes. Now, using the properties of sound in supercooled solids, one can emulate the resolution of electron scopes, although that is not much help to the student of living tissue!

Do we see with an acoustic microscope?

LOOKING WITH A MICROSCOPE

Do we see through a microscope? Let us first do away with the anachronistic word through. Looking through a lens was the first step in technology, then came peering through the tube of a compound microscope. Then, more to the point, we study photographs taken with a microscope. Thanks to the enormous focal length of an electron microscope it is natural to view the image on a large flat surface so everyone can stand around and point to what's interesting. Scanning microscopes necessarily present the image on a screen or plate. Any image can be digitized and retransmitted on a television display or whatever. Moreover digitization is marketable as the latest noise and even reconstituted lost information. Do not, however, become awed by technology. In the study of crystal structure, one good way to get rid of noise is to cut up a micrograph in a systematic way, paste it back together, and rephotograph it for interference contrast.

We do not in general see through a microscope; we see with one. But do we see with a microscope? It would be silly to debate the ontological status of a word, a word already put to innumerable uses of an entirely intellectual sort. "Now I see the point," and kindred employments in mathematics. Or consider how the physicist writes the hypothesis and the pithy sentence, from a lecture listing twelve fermions, or fundamental constituents of matter, including electron neutrinos, deuterons, etc. We are told that "of these fermions, only the t quark is yet unseen. The others constitute the nuclear 't states in e + e- annihilation at PETRA remains a puzzle. . . ."18 Seeing and observing for this high energy physicist are a long way from the eyes. It is probably seen is acquired its peculiar association with oculiar vision only at the start of the nineteenth century, as is manifested in the twin doctrines called positivism and phenomenology, the philosophies that say seeing is with the eye, not the mind.

Consider a device for low-flying jet planes, laden with nuclear weapons, skimming a few dozen yards from the surface of the earth in order to evade radar detection. The vertical and horizontal scale are both of interest to the pilot; he needs both to see a few hundred feet down and miles and miles away. So the visual information is digitized, processed, and cast on a head-up display on the windscreen. The distances are condensed and the altitude is expanded. Does the pilot see the terrain? I should say so. It would be foolish to put in some unnatural word like perceive to indicate that the seeing employee inside the image on a screen or plate. That is not one in which the pilot could have seen the terrain by getting off the plane and taking a good look. There is no way of getting a look at that much landscape without an instrument.

Consider the electron diffraction microscope with which I produce images either in conventional space or in reciprocal space. Reciprocal space is, roughly speaking, conventional space turned inside out; near is far and far is near. Crystallographers often find it most natural to study their specimens in reciprocal space. Do they see them in reciprocal space? No, so, and thereby call in question the Kantian doctrine of the uniqueness of perceptual space. How far could one push the concept of seeing? Suppose I take an electronic paint brush and paint a picture made by a computer of a rather accurate picture (I) of a cell that I have previously studied, say, by using a digitized and reconstituted image (II). Even if I am "looking at the cell" in case (II), in (I) I am only looking at a drawing. What is the real difference? The important feature is that in (II) there is a direct interaction between a wave source, an object, and a series of physical events that end up in an image of the object. To use quotation [B] once again, in case (II) we have a map of interactions between the specimen and the imaging radiation. If the map is a good one, then (II) is seeing with a "microscope."

This is doubtless a liberal extension of the notion of seeing. We see with an acoustic microscope. We see with television, of course. We do not say that we saw an attempted assassination with the television, but on the television. That is mere idiom, inherited from "I heard it on the radio." We distinguish between seeing the television broadcast live or not. We have endless distinctions to be made with various adverbs,
adjectives, and even prepositions. I know of no confusion that will result from talk of seeing with a microscope.

SCIENTIFIC REALISM

When an image is a map of interactions between the specimen and the image of radiation, and the map is a good one, then we are seeing with a microscope. What is a good map? After discarding or disregarding aberrations or artefacts, the map should represent some structure in the specimen in essentially the same two- or three-dimensional set of relationships as are actually present in the specimen.

Does this bear on scientific realism? First let us ask if it can bear in only the modest way. I do not even argue here for the reality of objects and structure that can be discerned only by the electron microscope (That calls for another essay). I have spoken of light microscopy. Now imagine a reader initially attracted by van Fraassen and who thought that objects seen only with light microscopes do not count as observable. That reader could change his mind, and admit such objects into the class of observable entities. This would still leave intact all the main philosophical positions of van Fraassen's anti-realism.

But if we conclude that we see with the light microscopes, does it follow that the objects we report seeing are real? No. For I have said only that we should not be stuck in the nineteenth century rut of positivism-cum-phenomenology, and that we should allow ourselves to talk of seeing with a microscope. Such a recommendation implies a strong commitment to realism about microscopy, but it begins the question at issue. This is clear from my quotation from high-energy physics, with its cheerful talk of having seen electron neutrinos, deuterons, and so forth. The physicist is a realist, too, and he shows this by using the word see, but his usage is no argument that there are deuterons. Here perhaps is one source of the philosophers' scepticism of Dr. Parakh's suggestion that one can become a convinced realist because of advances in microscopy.

Does microscopy then beg the question of realism? No. On closer inspection, Parakh's suggestion is right. We are convinced of the structures that we observe using various kinds of microscopes. Our conviction arises partly from our success at systematically removing aberrations and artefacts. In 1800 there was no such success. Bichat banned the microscope from his dissecting rooms, for one did not, then, observe structures that could be confirmed to exist in the specimens. But now we have by and large got rid of aberrations; we have removed many artefacts, disregard others, and are always on the lookout for underhanded frauds. We are convinced about the structures we seem to see because we can interfere with them in quite physical ways, say by microinjection.

We are convinced because instruments using entirely different physical principles lead us to observe pretty much the same structures in the same specimen. We are convinced by our clear understanding of most of the physics used to build the instruments that enable us to see, but the theoretical conviction plays a relatively small part. We are more convinced by the admirable intersections with biochemistry, which confirm that the structures that we discern with the microscope are individuated by distinct chemical properties, too. We are convinced not by a high powered deductive theory about the cell—there is none—but because of a large number of interlocking low-level generalizations that enable us to control and create phenomena in the microscope. In short, we learn to move around in the microscopic world. Berkeley's New Theory of Vision may not be the whole truth about infantile binocular three-dimensional vision, but is surely on the right lines when we enter the new worlds within worlds that the microscope reveals to us.

**NOTES**

2. W. Shakespeare, Romeo and Juliet, 1.4.58, 66-67.

3. William B. Carpenter, The Microscope and Its Revelations, 8th ed., revised by W. H. Dallinger, London and Philadelphia, 1899. Quoted in S. H. Gage, The Microscope, 9th ed. (Ithaca: Comstock), 21. Gage contrasts the alternative theory that microscopic vision "is with the unaided eye, the telescope and the photographic camera. This is the original view, and the one which many are favoring at the present day." 

10. Quoted in Bradbury (note 1), 130.

13. S. H. Gage (note 3), 11th ed., 1916. The direct quotation from Carpenter and Dallinger is dropped in the 12th edition of 1917, but the spirit is retained, including the "nui generis." Gage does admit that "Certain very striking experiments have been devised to show the accuracy of Abbe's hypothesis, but as pointed out by many, the ordinary use of the microscope never involves the conditions realized in these experiments" (page 501). How Imre Lakatos would have delighted in this degenerating programme of preserving the naive picture of vision, complete with "monster-barring" of the striking experiments! This passage remained unchanged in essentials even in the 17th edition of 1941.

14. I owe a particular debt of gratitude to my friend R. J. Skaa of Peterhouse, Cambridge, who allowed me to spend a good deal of time in his cell biology laboratory in the Department of Haematological Medicine, Cambridge University.
